**ABSTRACT** The lack of available antibiotics is a global public health problem due to the emergence of antimicrobial resistance. Effective therapeutic regimens are urgently needed against *Escherichia coli* strains that produce the colistin resistance gene *mcr-1* and to inhibit the emergence of resistance. In this study, we assessed the antimicrobial activity of a series of concentrations of colistin-based combinations with rifampin and/or azithromycin against three strains of *Escherichia coli*, including colistin-resistant isolate MZ1501, isolate HE1704 that produces MCR-1, and colistin-susceptible isolate MZ1509. Experiments were conducted with a medium inoculum of \(~10^7\) CFU/ml over 48 h. Subsequently, the in vivo therapeutic effect was investigated using a neutropenic mouse thigh infection model. Almost all monotherapies showed unsatisfactory antibacterial activity against *E. coli* isolates producing MCR-1. In contrast, colistin in combination with rifampin or azithromycin resulted in an obvious decrease in the bacterial burden albeit with regrowth. More obviously, synergistic antimicrobial activity of colistin-based triple-combination therapy with rifampin and azithromycin was observed, resulting in a rapid and exhaustive antibacterial effect. In vivo treatments confirmed these findings, where mean decreases of 0.38 to \(0.90\) log_{10} CFU and 1.27 to \(1.78\) log_{10} CFU were noted after 24 h and 48 h of treatment, respectively, against colistin-resistant *E. coli* strains when 5 mg/kg of body weight of colistin was combined with rifampin and azithromycin. Colistin-based combinations with rifampin and azithromycin provide a more active therapeutic regimen than monotherapy or colistin-based double combinations against *E. coli* producing MCR-1.

**KEYWORDS** colistin, rifampin, azithromycin, *Escherichia coli*, mcr-1
Gram-negative infections because of poor diffusion across the outer membrane of most Gram-negative bacteria (12). However, disruption of the outer membrane of Gram-negative bacteria by colistin may contribute to the uptake of azithromycin. Enhanced antimicrobial activity of azithromycin against *Pseudomonas aeruginosa* in serum and bronchoalveolar lavage fluid through increased outer membrane permeability and reduced efflux of the drug has been reported (13). The immunomodulatory activity of azithromycin has also been of great interest in recent years (14). Thus, the objective of this work was to evaluate the in vitro synergistic effect of colistin-based combinations with rifampin and/or azithromycin against colistin-resistant *Escherichia coli* isolates producing MCR-1 and sensitive *E. coli* isolates. An in vivo model to verify treatment was performed using a neutropenic mouse thigh infection model. This work aimed to provide a feasible antibiotic regimen consisting of colistin, rifampin, and azithromycin against colistin-resistant *E. coli* infections.

**RESULTS**

**Time-kill assays. Monotherapy.** Time-kill curves for colistin, rifampin, and azithromycin treatments against *E. coli* strains MZ1501<sup>R</sup>, HE1704<sup>R</sup>, and MZ1509<sup>S</sup> are shown in Fig. 1. Data represent the change in bacterial burden from an initial inoculum of 10<sup>7</sup> CFU/ml. For *E. coli* strain MZ1501<sup>R</sup> and strain HE1704<sup>R</sup> that produces MCR-1, the time curves for colistin concentrations of 0.5 to 4 mg/liter had a synchronous growth tendency with growth control. A colistin concentration of 8 mg/liter resulted in an early bactericidal effect (≥3-log<sub>10</sub> decrease in colony counts) by 4 h but regrowth of bacteria after 6 h. Unsurprisingly, for the colistin-sensitive *E. coli* strain MZ1509<sup>S</sup>, colistin at 1 to 8 mg/liter performed effectively. Unfortunately, all rifampin (0.5, 1, and 2 mg/liter) and azithromycin (0.5, 1, and 2.5 mg/liter) concentrations showed no evidence of inhibition of any of the strains through 48 h.

**Double-combination therapy.** The time curves for the addition of rifampin and azithromycin to colistin against *E. coli* MZ1501<sup>R</sup>, HE1704<sup>R</sup>, and MZ1509<sup>S</sup> are shown in
Fig. 2. The accompanying pharmacodynamics analysis is also presented in Table S1 in the supplemental material. Increased antibacterial activity against MZ1501R and delayed recovery of growth were noticed when colistin-based combinations with rifampin or azithromycin were used, except when 0.5 mg/liter colistin was combined with 0.5 mg/liter rifampin or azithromycin. A virtual bactericidal effect was observed with a reduction of approximately 3 log10 CFU/ml from the initial burden of ~10^7 CFU/ml within 4 to 6 h when 1 or 2 mg/liter colistin was employed in combination with 0.5 to 2 mg/liter rifampin. Furthermore, the combination of 1 or 2 mg/liter colistin with 2.5 mg/liter azithromycin achieved an eradication effect (>4-log10 decrease in colony counts) by 48 h, without regrowth (Fig. 2a, d, and g). Quite different from the MZ1501R isolate, colistin-based double combinations showed weaker antimicrobial activity against HE1704R due to simultaneous colistin and azithromycin resistance, with at most a 2-log10 CFU/ml reduction (Fig. 2b, e, and h). Early antimicrobial activity against MZ1509S was noted, where the numbers of bacteria were reduced to near the limit of detection by 4 h, followed by a quick recovery when 0.5 mg/liter colistin combined with rifampin or azithromycin was used. An eradication effect on isolate MZ1509S was achieved by 6 h, without regrowth, when 1 or 2 mg/liter colistin was combined with rifampin or azithromycin (Fig. 2c, f, and i).

**Triple-combination therapy.** The *in vitro* antibacterial activity of a triple combination comprising colistin, rifampin, and azithromycin was assessed by performing time-
The results are presented in Fig. 3 and Table S2 in the supplemental material. All colistin-based simultaneous combinations of rifampin and azithromycin displayed earlier bactericidal action against MZ1501R than the corresponding double combinations. Apart from the combinations of three drugs at low concentrations that resulted in regrowth after 8 h, triple combinations achieved bacterial eradication effects at 12 h with 0.5 or 1 mg/liter colistin and at 6 h with 2 mg/liter colistin when high concentrations of rifampin and azithromycin were used (Fig. 3a, d, and g). No evident enhancement of the antimicrobial effect against HE1704R was observed with triple combinations with 0.5 or 1 mg/liter colistin compared with double combinations. Synergistic effects were observed at 24 h with combinations with 2 mg/liter colistin, and bacteria were undetectable at 48 h (Fig. 3b, e, and h). For MZ1509S, triple combinations with 0.5 mg/liter colistin exhibited more-rapid antimicrobial action by 4 h than double combinations. Unsurprisingly, high concentrations of the triple combination resulted in complete eradication by 0 to 4 h (Fig. 3c, f, and i).

**Pharmacokinetics validation.** The plasma pharmacokinetic (PK) parameters for subcutaneously injected colistin and intragastric administration of rifampin and azithromycin are presented in Table 1. The maximum concentrations of drug in plasma ($C_{\text{max}}$) for 2.5 and 5 mg/kg of body weight of colistin, 10 mg/kg rifampin, and 100 mg/kg...
azithromycin were 3.08 mg/liter, 5.93 mg/liter, 14.20 mg/liter, and 4.12 mg/liter, respectively. The time to maximum concentration of drug in plasma ($T_{\text{max}}$) for colistin, rifampin, and azithromycin varied from 0.50 to 2.00 h. The unbound peak concentrations of colistin were approximately 0.26 and 0.50 mg/liter based on a previous report in which the unbound fraction of colistin was approximately 8.4% in neutropenic mice (15). Similarly, the free fraction of rifampin was found to be 16.2% in mice (16), and the free peak drug concentration here was calculated to be approximately 2.30 mg/liter, which was close to the concentration employed in in vitro time-kill tests. Given that there is a large difference in plasma protein binding among different azithromycin concentrations (the plasma protein binding of azithromycin declined from approximately 50% at 0.05 mg/liter to 12% at 0.5 mg/liter [17]), the unbound peak concentration of azithromycin may be higher than or close to the concentration used in time-kill tests.

**In vivo treatment verification.** To confirm the antibacterial activity of colistin-based combinations with rifampin and/or azithromycin, the in vivo pharmacodynamics of the administration of 2.5 and 5 mg/kg colistin by subcutaneous injection, and the accompanying intragastric administration of 10 mg/kg rifampin and 100 mg/kg azithromycin, were assessed. Regimens comprising a single agent or colistin-based double or triple combinations were assessed in a neutropenic mouse infection model by injecting the *E. coli* MZ1501R, HE1704R, or MZ1509S strain into animals. The results are shown in Fig. 4 and 5. Neither colistin every 12 h nor rifampin or azithromycin every 24 h alone could inhibit *E. coli* MZ1501R or HE1704R over a 48-h period in this study. Slight inhibition against MZ1501R was observed after treatment for 24 h when rifampin was added to 5 mg/kg colistin, whereas this treatment was almost useless against HE1704R.

**FIG 4** In vivo pharmacodynamics of colistin sulfate at 2.5 and 5 mg/kg, rifampin at 10 mg/kg, and azithromycin at 100 mg/kg, alone and in colistin-based double and triple combinations, against colistin-resistant strains MZ1501R and HE1704R. A growth control without drug administration was included in all tests.
over a 48-h period (0.13- to 0.4-log₁₀ CFU increase). This decrease in bacterial burden did not occur in mice that experienced concurrent treatment with colistin and azithromycin against MZ1501R and HE1704R. Higher activity than those of double combinations was noted when colistin was combined with rifampin and azithromycin concurrently. A 0.30- to 0.60-log₁₀ CFU decrease with combinations with 2.5 mg/kg colistin and a 1.27- to 1.78-log₁₀ CFU decrease with combinations with 5 mg/kg colistin were observed for colistin-resistant strains MZ1501R and HE1704R after 48 h of therapy (Fig. 4). For colistin-susceptible strain MZ1509S, even colistin alone at 2.5 mg/kg reduced the bacterial burden in mouse thighs. Notably, eradication of the MZ1509S strain was observed in mice treated with double or triple combinations containing 5 mg/kg colistin for 48 h or 24 h (Fig. 5).

**DISCUSSION**

Polymyxins had been banished from the family of clinical antibiotics due to their many and various side-effects. The continual emergence of Gram-negative bacteria producing β-lactamases and carbapenemases, which can resist a variety of antibiotics, and the sluggish development of new drugs that possess independent target mechanisms have led to the reuse of polymyxins. However, the rapid spread of the plasmid-mediated *mcr-1* gene in recent years has dealt a devastating blow to the effective use of polymyxins. In this instance, polymyxin-based combination therapy using old drugs might be an optional therapeutic measure for drug-resistant strains.

Antibacterial activity of colistin with amikacin against *E. coli* strains coproducing NDM-5 and MCR-1 has been reported, where augmented susceptibility to colistin and depressed bacterial burdens were observed (18). Polymyxin B in combination with rifampin and meropenem against highly polymyxin B-resistant KPC-producing *Klebsiella pneumoniae* may be a viable option, since the triple-drug combination displayed early bactericidal activity against organisms within 8 h and thereafter (9). Giamarellos-Bourbonis et al. reported that the activity of colistin against *Acinetobacter baumannii* was increased in the presence of rifampin in time-kill studies (19). Bassetti et al. studied the clinical and microbiological responses and the safety of simultaneous intravenous treatment with colistin sulfomethate sodium and rifampin. No renal failure or neurotoxicity was observed among patients with normal baseline renal function, which indicated that combination treatment with colistin and rifampin was effective and safe for severe infections caused by multidrug-resistant *A. baumannii* (20).

Synergy is defined as a reduction in colony counts of ≥100-fold or 2 log₁₀ units for 24 h following treatment with a combination compared with the most active single agent alone and a ≥100-fold decrease in colony counts from the initial burden (21). In

**FIG 5** In vivo pharmacodynamics of colistin sulfate at 2.5 and 5 mg/kg, rifampin at 10 mg/kg, and azithromycin at 100 mg/kg alone and in colistin-based double and triple combinations against colistin-susceptible strain MZ1509S. A growth control without drug administration was included in all tests.
our study, the in vitro pharmacodynamics proved that clinically available concentrations of colistin, rifampin, and azithromycin alone are ineffective against E. coli isolates producing MCR-1. Furthermore, in vivo treatment with lower/routine therapeutic dosages close to the concentrations used in in vitro time-kill pharmacodynamics studies verified this point. The combination of colistin and high concentrations of rifampin (2 mg/liter) or azithromycin (2.5 mg/liter) against colistin-resistant E. coli isolates in vitro was found to be synergistic at one-quarter to one-half the MIC of colistin in this study. However, this double-combination treatment strategy failed to control the regrowth of strain HE1704<sup>a</sup>. The combination of colistin and rifampin showed higher antimicrobial activity against a colistin-resistant isolate than the combination of colistin and azithromycin, but the opposite was true for the colistin-sensitive isolate. As expected, colistin in combination with both rifampin and azithromycin resulted in more-efficient anti-bacterial activity than colistin-based double combinations against colistin-sensitive or -resistant strains in vitro. More importantly, for E. coli strain MZ1501<sup>b</sup>, we noted that the combination of one-eighth the MIC of colistin plus 2 mg/liter rifampin and 0.5 mg/liter azithromycin was able to stop regrowth within 8 to 12 h.

To estimate the in vivo pharmacodynamics of drug combinations of colistin plus rifampin and/or azithromycin, a neutropenic mouse infection model was used over 48 h in our study (to our knowledge, we believe that this is the first time that such an observation has been made). As might be expected, colistin (2.5 and 5 mg/kg) in combination with rifampin or azithromycin displayed the same effects against colistin-resistant E. coli strains as those observed in the in vitro time-kill experiments, with the bacterial burden hardly being affected (Fig. 2 and 4). A significant change in terms of the reduction of the bacterial burden was observed when the same dosage-based triple combination was employed. This was clearly the case when triple combinations containing 5-mg/kg colistin were used against E. coli strains, and a continuous decrease in the bacterial burden occurred in infected thighs by 0 to 48 h.

The recommended regimen of colistin methanesulfonate sodium (CMS) is 90 mg of colistin base activity (CBA) (equivalent to 3 million IU) every 8 h, following a loading dose of 270 mg of CBA in patients with normal renal function by intravenous administration. PK research with intravenous infusion of CMS at 3 million IU every 8 h for adult patients showed that the $C_{\max}$ in plasma was 2.36 mg/liter in the steady state (22), which was lower than the mean serum $C_{\max}$ values (3.34 mg/liter) at the same dose obtained in other studies (23) and close to the peak plasma concentration (3.08 mg/liter) of colistin in mice treated with 2.5 mg/kg colistin sulfate in this study. However, consistent with previous research showing that the currently used dose might not provide the most effective therapy against Pseudomonas aeruginosa in adult patients (23), treatment adopting colistin at 2.5 or 5 mg/kg for infection caused by colistin-resistant E. coli proved to be ineffective. The recommended oral dosages for rifampin and azithromycin are 10 mg/kg and 500 mg, respectively, in clinical practice. The plasma $C_{\max}$ of oral rifampin taken at 10 mg/kg once daily is approximately 10.0 mg/liter in patients (24), which is close to the $C_{\max}$ (14.2 mg/liter) measured in this study. Therefore, the pharmacodynamics of 10 mg/kg rifampin in mice can reflect the actual status in clinical practice to some extent. Previous research showed that the dose and $C_{\max}$ of azithromycin required for equivalent efficacy in murine models are considerably higher than those required in humans due to the higher rate of azithromycin clearance in mice (25). Therefore, an azithromycin dosage of 100 mg/kg was used in the in vivo pharmacodynamics experiments according to the conversion criterion based on body surface area in the Food and Drug Administration’s Guidance for Industry: Estimating the Maximum Safe Starting Dose in Initial Clinical Trials for Therapeutics in Adult Healthy Volunteers (26). However, from the results of in vivo PK experiments, treatment using the recommended dose of azithromycin (100 mg/kg) was ineffective against E. coli, even if the MIC value of azithromycin was below the susceptibility breakpoint for Enterobacteriaceae according to Clinical and Laboratory Standards Institute (CLSI) breakpoint recommendations (27).

According to a previous report, bactericidal antibiotics can stimulate the production...
of hydroxyl radicals that contribute to bactericidal antibiotic-mediated cell death (28). It remains to be seen whether synergistic antibacterial action can be explained by an increased production of hydroxyl radicals, which could be stimulated by colistin-based combination therapy with rifampin and azithromycin. In addition, colistin destroys the outer membrane of Gram-negative bacteria and thereby increases the amounts of increased production of hydroxyl radicals, which could be stimulated by colistin-based combination therapy with rifampin and azithromycin against colistin resistant isolate MZ1501\textsuperscript{a} and colistin-susceptible isolate MZ1509\textsuperscript{b}, and colistin-resistant isolate HE1704R was isolated from the fecal samples of a breeder from the same chicken farm in this study. The susceptibilities of the selected isolates and the quality control isolate (ATCC 25922) to colistin, polymyxin B, rifampin, azithromycin, amikacin, ciprofloxacin, ampicillin, ampicillin-sulbactam, cefotaxime, and imipenem were determined in triplicate by adopting the broth microdilution method using cation-adjusted Mueller-Hinton (MH) broth (Becton, Dickinson and Company, Sparks, MD). The susceptibility breakpoints for all drugs were interpreted according to CLSI breakpoint recommendations. PCR amplification of mcr-1 for the selected isolates was conducted according to a previously reported method (5). The PCR products underwent sequence determination by the Beijing Genomics Institute (Guangzhou, China). Nucleotide sequences were typed into BLAST to analyze identities with published sequences. The MICs and genotypes of selected isolates are shown in Table 2.

**Antibiotics and media.** Colistin sulfate, rifampin, and azithromycin powders were purchased from Sigma-Aldrich and hydrated with free water, methyl alcohol, and 95% ethanol, respectively. Next, all drugs were filtered for sterilization by using 0.22-μm nylon syringe filters (Fisher Scientific, Pittsburgh, PA) before dilution with culture medium at the moment of testing (the content of methyl alcohol and 95% ethanol in the broth was less than 5%, and antibacterial tests against strains were performed concurrently with the same concentration of methyl alcohol and 95% ethanol in the broth). Cation-adjusted Mueller-Hinton broth (25.0 mg/liter Ca\textsuperscript{2+} and 12.5 mg/liter Mg\textsuperscript{2+}) (Becton, Dickinson and Company, Sparks, MD) was used in all experiments.

**Static time-kill assays.** To determine whether the effect of colistin combined simultaneously with rifampin and azithromycin was comparable to those of colistin, rifampin, and azithromycin alone or as a combination of two antibiotics between them, a 48-h time course was needed to evaluate the rate and extent of killing. Series of drug concentrations of colistin (0.5, 1, 2, 4, and 8 mg/liter), rifampin (0.5, 1, and 2 mg/liter), and azithromycin (0.5, 1, and 2.5 mg/liter) were close to or higher than the clinically or preclinically attainable unbound plasma concentrations (15, 16, 25, 29, 30). Three-by-three (colistin at 0.5, 1, and 2 mg/liter combined, respectively, with rifampin at 0.5, 1, and 2 mg/liter or azithromycin at 0.5, 1, and 2.5 mg/liter) and three-by-three-by-two (colistin at 0.5, 1, and 2 mg/liter combined, respectively, with rifampin at 0.5, 1, and 2 mg/liter and azithromycin at 0.5 and 2.5 mg/liter) concentration procedures were performed on both strains. A single bacterial colony from a plate was incubated overnight in preprepared cation-adjusted MH broth to attain a concentration of ~10\textsuperscript{6} CFU/ml. Next, the antibiotics

were added to a logarithmic-phase culture at ∼10^7 CFU/mL, which was obtained by taking a supplement of fresh medium. At the time points of 0, 1, 2, 4, 6, 8, 12, 24, 28, 32, 36, and 48 h after incubation, 100 μL of each sample was withdrawn for colony counting. The lower limit of quantification was 2.0 log_{10} CFU/mL. A growth control was performed in each experiment.

**Pharmacokinetics in the mouse model.** Six-week-old specific-pathogen-free male ICR mice weighing 24 to 27 g (Laboratory Animal Center of South China Agricultural University, China) were used in this experiment. The animals were raised in accordance with national standards for laboratory animals in China (33). Thirty-six mice in each dosage regimen were separated into nine groups, in which four mice were named mice A to D. Colistin sulfate (2.5 or 5 mg/kg) with subcutaneous injection in the neck region was accompanied by intragastric administration with both rifampin (10 mg/kg) and azithromycin (100 mg/kg) in thiugh-infected neutropenic mice. We referred to the dosing strategies in other reports and tried to match the in vitro antimicrobial concentrations (25, 29, 30). Animals were then humanely killed, and blood samples were collected from a central vein at the given time (n = 4 mice per time point). Drug concentrations in the plasma of all A/B/C/D mice in different groups were used to calculate the PK parameters. The experimental protocol was approved by the Committee on the Ethics of Animals of South China Agricultural University.

**Analysis method.** The concentrations of colistin in plasma were determined by using a previously reported method that had been modified (31). Another method for the determination of rifampin and azithromycin concentrations was developed in this study. Briefly, an aliquot of 100-μL plasma samples was mixed with 50 μL 0.1% formic acid in water, followed by 250 μL methanol. After vortexing, the mixtures were centrifuged at 1,080 × g for 10 min at 4 °C. The supernatants were refined by using a 0.22-μm nylon syringe filter. Finally, an analysis was undertaken using ultraperformance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS). The entire analysis procedure was performed in the dark due to the photosensitivity of rifampin. Concentrations of colistin (390.8/101.1 [precursor ion/product ion] for colistin A and 386.2/101.0 [precursor ion/product ion] for colistin B), rifampin (823.8/791.5), and azithromycin (749.7/591.4) were determined simultaneously under a gradient elution program involving 0.1% formic acid in water (buffer A) and 0.1% formic acid in acetonitrile (buffer B) at a flow rate of 0.20 ml/min. The gradient elution program involved 6% buffer B from 0.0 to 1 min and an increase from 50% buffer B to 70% buffer B from 3.0 to 8.0 min; the ratio of buffer A and B is maintained from 8.1 min to 10 min. The limits of quantification for colistin, rifampin, and azithromycin ranged from 0.1 to 20 μg/liter. The rates of recovery of all drugs ranged between 84.4 and 115.0%. The inter- and intra-assay coefficients of variation were <10%. Pharmacokinetic parameters for three drugs in plasma samples were obtained by submitting the concentration-time data to WinNonlin software, version 5.2.1, for noncompartmental analysis.

**Neutropenic mouse thigh infection model and in vivo treatment.** Neutropenic (defined as neutrophil counts of ≤100 neutrophils/mm^3) mice were generated by the intraperitoneal injection of cyclophosphamide (Puboxin Biotechnology Co., Ltd., Beijing, China) 4 days before the 150-mg/kg dose and 1 day before the 100-mg/kg dose prior to thigh infection (32). Mice were infected by injecting 0.1 ml of a logarithmic-phase bacterial suspension (10^6 to 10^7 CFU/ml) intramuscularly into each thigh (four thighs in each group).

In vivo treatments were conducted 2 h after inoculation to verify the difference in antimicrobial effects between monotherapy and the drug combinations. Colistin sulfate (2.5 and 5 mg/kg) was administered by subcutaneous injection every 12 h, while rifampin (10 mg/kg) and azithromycin (100 mg/kg) were given to mice by intragastric administration every 24 h. The mice were euthanized after 24 h or 48 h of the procedure. Next, four thighs from each group were immediately separated and homogenized in 10 ml of precooled 0.9% sterile saline. The serial dilutions of thigh homogenates were plated onto MH agar plates for CFU determination and incubated overnight at 37 °C. Untreated control mice were sacrificed at the same time.
